Value of Active Buildings in the Future Great Britain's Energy System

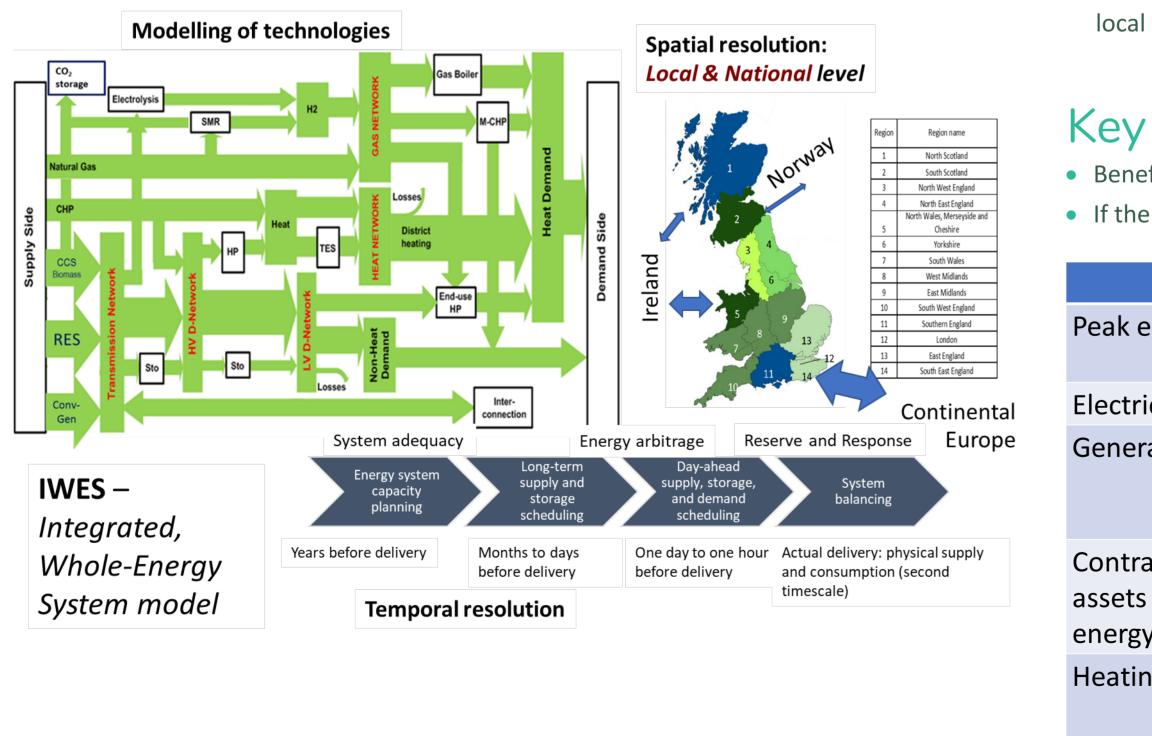

Introduction

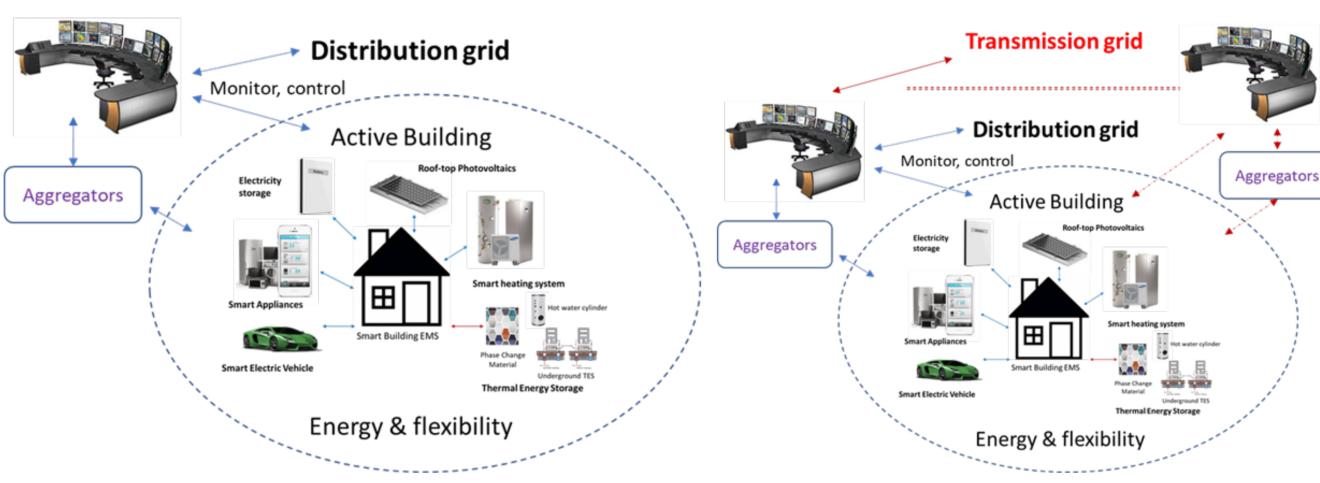

The slogan 'Think globally, act locally' has been an integral part of developing business strategies and climate actions, but how relevant it is in the context of Active Buildings (AB)? The transformation from passive to AB enables heat and electricity demand or generation to be controlled and adjusted. The objective is often to minimise peak demand, improve self-consumption of energy generated locally from solar PV or solar thermal, and reduce the building's carbon footprint. The key question is whether **minimising** the impact of increased electrification or distributed generation connection on the local energy system using the AB's flexibility will be the best strategy or shall we optimise the AB's flexibility from the whole-system perspective?

Modelling approach

To study the interaction across multienergy vectors (electricity, heat, hydrogen) and analyse the impacts of local or whole-system optimisation for AB's flexibility on the UK energy infrastructure, a set of case studies were simulated and optimised using the Integrated Whole-Energy System (IWES). The IWES model incorporates spatial and temporal details to determine the optimal investment and operating strategies for all system components to achieve the carbon target. The model is shown below.

Objective:

- Modulate demand and generation (arbitrage)
- Balancing (frequency response and operating reserve) services

Local-system approach

Whole-system approach

Minimise whole-system cost using the AB flexibility

AB functionalities:

- Provide system ancillary services
- Network congestion management for both local and national gird

Objective:

Minimise reinforcement cost of local distribution network using the AB flexibility

AB functionalities:

- Minimise peak demand
- Improve self-energy consumption at the local grid system
- Provide flexibility to alleviate local network constraints

Key findings

• Benefits of system flexibility: 15 - 17 £bn/year

• If the flexibility from AB is used only to minimise local system cost, it will increase the annual system cost by £1.5bn/year.

	Whole-system approach	Local prioritisation
electricity	More distribution networks (to access flexibility from ABs)	Less distribution networks
ricity distribution	Larger capacity	Less capacity
ration	More large-scale low-carbon generators at Tx More peaking capacity	More smaller low-carbon DG (e. PV) at Dx Less peaking capacity
racted capacity of flexibility s (e.g. demand response, gy storage)	Lower	Higher
ng appliances	Optimal mix between low-cost resistive heating and high-cost heat pumps	Heat pumps
